### ABSTRACT

Many studies of animal distributions use habitat and climactic variables to explain patterns of observed space use. However, without behavioral information, we can only speculate as to why and how these characteristics are important to species persistence.

Animal-borne accelerometer and magnetometer data loggers can be used to detect behaviors and when coupled with telemetry improve our understanding of animal space use and habitat requirements. However, these loggers collect tremendous quantities of data requiring automated machine learning techniques to identify patterns in the data. Supervised machine learning requires a set of training signals with known behaviors to train the model to identify the unique signal characteristics associated with each behavior. In contrast, unsupervised approaches aggregate unlabeled signals into groups based purely on signal similarity but, without additional information, do not identify specific behaviors.

In this paper, we propose a probabilistic framework for interpreting uncertainty in machine learning techniques—the probability profile—and demonstrate how to *post hoc* identify behaviors within signal groups. We assess model performance using a matrix-based measure of dissimilarity. We used a Random Forest (RF) and a clustered self-organizing map (CSOM) for comparison and demonstrate the use of a behavioral profile for each using a data set of high-frequency accelerometer and magnetometer data collected from 7 captive wild pigs (*Sus scrofa*) moving in a 1 ha outdoor enclosure.

We found that the RF had more discrimination than the CSOM which had fewer clusters associated with high probabilities of a single behavior (>50%). The leave-*p*-out cross validation statistic of the probability matrix ( $\bar{L}^1$ ) indicated that there was an average maximum dissimilarity of 20% and 65% between the training and test data sets for the RF and CSOM methods, respectively.

Using a probability profile to describe groups predicted from machine learning allows the variation and error inherent in behavioral prediction to be incorporated directly into the model to better reflect the nuances of behavior derived from accelerometer and/or magnetometer signals. We discuss the data requirements of this framework, demonstrate its application to field data, highlight critical assumptions and caveats, and examine how it may be used to generate new ecological inference.

### 1. Introduction

A central aim of ecology is to understand the environmental drivers

of fitness and the spatial distribution of individuals. Resources (e.g., energy, water, nutrients) are required for animal survival, growth, and reproduction, thus resource availability is an important predictor of

animal fitness (Brown et al., 2004; Matthiopoulos et al., 2015). How organisms seek and acquire resources can also be influenced by predation risk (DeCesare et al., 2014), thermoregulation (Street et al., 2016), social interactions (Cozzi et al., 2018), and landscape structure (Beyer et al., 2016). Therefore, animal spatial distributions are the result of interacting and competing immediate and long-term needs (Nathan et al., 2008). Species-distribution models use knowledge of habitat and behavioral requirements to explain observed patterns of use (Boyce and McDonald, 1999; Elith and Leathwick, 2009; Guisan and Thuiller, 2005); however, individuals may exhibit variation in space use across habitat types or utilize a single landscape for multiple purposes (Mitchell et al., 2020; Street et al., 2016). Quantifying this variation is an important step in understanding animal distributions (Johnson, 1980; Matthiopoulos et al., 2015; Nathan et al., 2008; Van Horne, 1982).

Early studies used direct observation to study animal space use, yet many animals are difficult to observe in situ resulting in low sample sizes, human-observer bias and/or detection bias (Aebischer et al., 1993; Altmann, 1974; Burghardt et al., 2012; Johnson, 1980). Telemetry and GPS reduce these issues by allowing animals to be relocated from a distance (Cochran and Rexford, 1963; Rodgers et al., 1996). Many approaches exist to associate animal spatial locations with habitat characteristics including compositional analysis (Aebischer et al., 1993), Resource- and Step-Selection Functions (Boyce and McDonald, 1999; Fortin et al., 2005), and Poisson point-process models (Warton and Shepherd, 2010). However, these approaches are often coarse in scale and thus divorced from the decision-making processes made by animals on a per-step basis. Further, these models are correlative, and the behavioral drivers of animal presence must be inferred or hypothesized from model outputs. Characteristics of movement tracks such as step length and turning angle may be used to identify coarse behavioral states such as “encamped” and “exploratory” behavioral states, thereby improving the accuracy of distribution models (Abrahms et al., 2017; Auger-Méthé et al., 2016; Morales et al., 2004), but these states are also correlative. For example, a small step length and broad turning angle are often associated with an encamped state (Morales et al., 2004), but numerous animal behaviors may occur within that state so long as they are characterized by similar steps and angles (e.g., fighting, resting, area-restricted foraging, etc.). These states may be better thought of as “movement modes”, and without additional information such modes cannot explicitly identify the behaviors performed in a particular state.

Animal-borne accelerometer and magnetometer dataloggers measure the change in speed, direction, and orientation of an animal in the longitudinal, lateral, and dorso-ventral (X-, Y-, and Z-) axes allowing for more detailed behavioral identification (Abrahms et al., 2017; Brown et al., 2013; Shepard et al., 2008; Williams et al., 2020; Wilson et al., 2008). In such a data set, a behavior such as resting may be sensed as a lateral orientation with little to no acceleration versus walking as an upright orientation with oscillations corresponding to each step (Chakravarty et al., 2019; Wilson et al., 2018). However, for many behaviors high sampling frequencies are required for detailed resolution of signals. While these signals can be distinguished visually, loggers often produce tremendous quantities of data requiring automated techniques such as decision trees, Random Forests (RFs), and Artificial Neural Networks (ANN; Halsey et al., 2009; Nathan et al., 2012; Wang and Xu, 2015; Yoda et al., 2001) to identify the behaviors associated with a given signal. Much accelerometer research has applied machine learning techniques in a supervised manner which requires *a priori* labeling of training signals with known behaviors so that the trained model can classify similar signals throughout the full data (Chakravarty et al., 2020; Leos-Barajas et al., 2017; Nathan et al., 2012). These approaches predict the behavior associated with a signal based on its similarity to the training signal but are limited to pre-defined behaviors for signal identification (Nathan et al., 2012; Wang and Xu, 2015). By contrast, unsupervised approaches group the data signals based purely on similarity, but biological interpretation of the signal groups identified requires additional *post hoc* attention (Chimienti et al., 2016; Sakamoto

et al., 2009). This has often been accomplished by using auxiliary information such as depth or altitude to determine the behavior or behaviors within the groups (Sakamoto et al., 2009).

This is further complicated by the highly subjective nature of behavior and the rarity of standardized ethograms (Stanton et al., 2015). Behaviors can be characterized on multiple scales and depending on the definition, a single behavior may be characterized by multiple signals which may occur in different groups or be so similar in their movement characteristics as to be indistinguishable. For example, behaviors such as grazing and browsing have different head postures and may produce distinct signals, though both may be classified by the analyst as foraging. Conversely, a single signal may be shared across many behaviors; sniffing and rooting may share a head-down and meandering trajectory but have different implications for the animal (one is searching, and the other is consuming). Traditionally, a signal group (cluster or class) would be defined as its majority behavior and other behaviors that produce the same signal determine the error rate (e.g., Nathan et al., 2012). Although we may see variation in a signal group due to model error, this can be assessed through model validation; still, a well validated model that assigns a group its majority behavior ignores much of the potential for biomechanical similarity among behavioral signals and unrealistically simplifies behavior. The aggregated error may reveal interesting behavior-specific trends such as signal commonalities between behaviors or unique signals from a single behavior. Understanding the probability of observing one of many possible behaviors (rather than a single behavior) given a data signal can lead to new tools and insights in theoretical and applied ecology. Here we propose a framework to investigate variation in behavioral classification and clustering by explicitly characterizing the probability of observing target behaviors given a data signal. We demonstrate the construction of stochastic matrices for unique data signals (groups) and develop a cross-validation procedure with matrix-based validation metrics to evaluate model fit and the consistency of predicted behavioral profiles. Our framework can be applied using either supervised and unsupervised approaches to identify behaviors from biologger data, and we demonstrate the application and interpretation of outputs using both approaches applied to empirical data.

## 2. Methods

### 2.1. Workflow overview

Our proposed approach uses two data sources: (1) a time-series of accelerometer and magnetometer signals and (2) temporally explicit behavioral observations collected simultaneously. Using these two data streams our workflow is:

- (1) Combine accelerometer and magnetometer data with behavioral observations.
- (2) Process the data to reduce noise and compress the data over a time interval.
- (3) Perform a machine learning method to group the signals.
- (4) Construct a matrix of stochastic vectors for the behavioral probabilities given data signals.
- (5) Evaluate the predictive accuracy of the matrix given new data.

There is a large body of literature on the deployment and use of accelerometers and magnetometers (Brown et al., 2013; Williams et al., 2020; Wilson et al., 2008) and on classifying animal behaviors from direct observation (Chakravarty et al., 2020; Nathan et al., 2012; Shepard et al., 2008; Wilson et al., 2020; Yoda et al., 2001). As such we do not discuss these here and presume that readers have already collected the relevant data (Fig. 1).

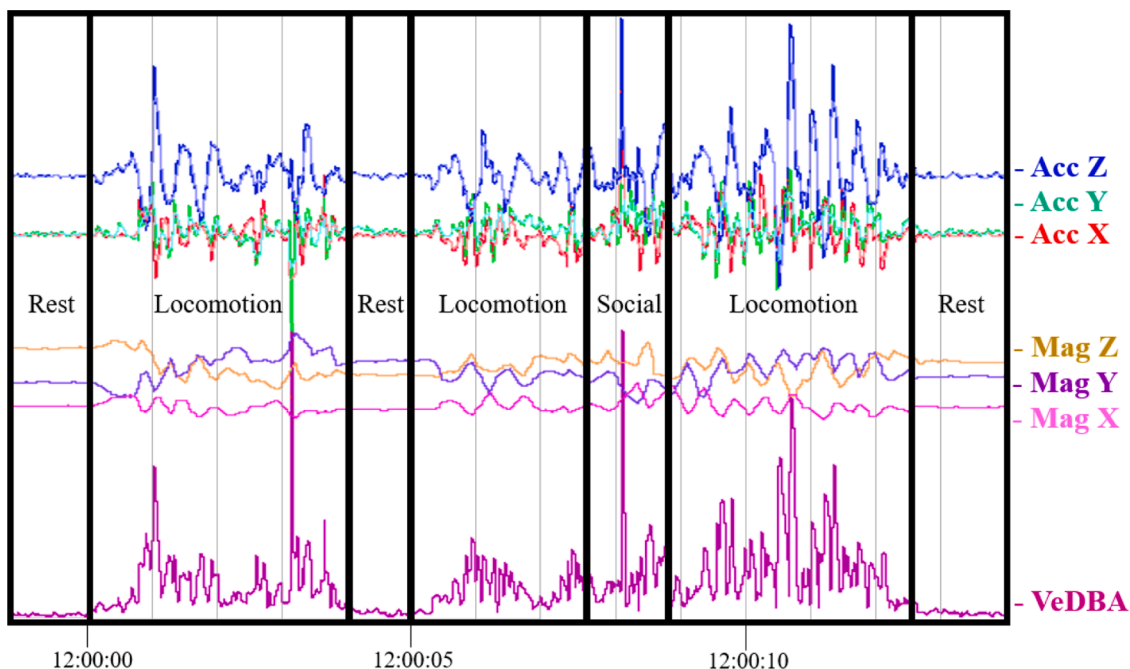

Figure 1. A time series of accelerometer and magnetometer signals annotated with observed behaviors.

2.2. Data preprocessing

There are many ways to preprocess accelerometer/magnetometer (hereafter, AM) data for analysis, but these often involve calculating additional metrics, smoothing and dimensionality reduction. Animal-borne accelerometers measure both the dynamic acceleration due to animal movement and the static pull of Earth’s gravitational field. Thus, many separate the raw acceleration into the static and dynamic components of acceleration (Shepard et al., 2008). The dynamic acceleration can then be used to derive proxies for energy expenditure, such as

VeDBA, the vectorial sum of dynamic body acceleration, or ODBA, Overall Dynamic Body Acceleration (Gleiss et al., 2011; Qasem et al., 2012; Wilson et al., 2020). But regardless of the input channels chosen by the analyst, accelerometer and magnetometer measurements are often noisy and require smoothing of data channels to isolate the signals from the noise (Viviani et al., 2005). Given an appropriate smoothing procedure, smoothed signals may be evenly resampled and subsequently subjected to dimensionality reduction (Fig. 2; Appendix VI: 5). Many analysts choose a fixed time-period segmentation (e.g., 1 s) and summarize the data over this period using running averages and standard

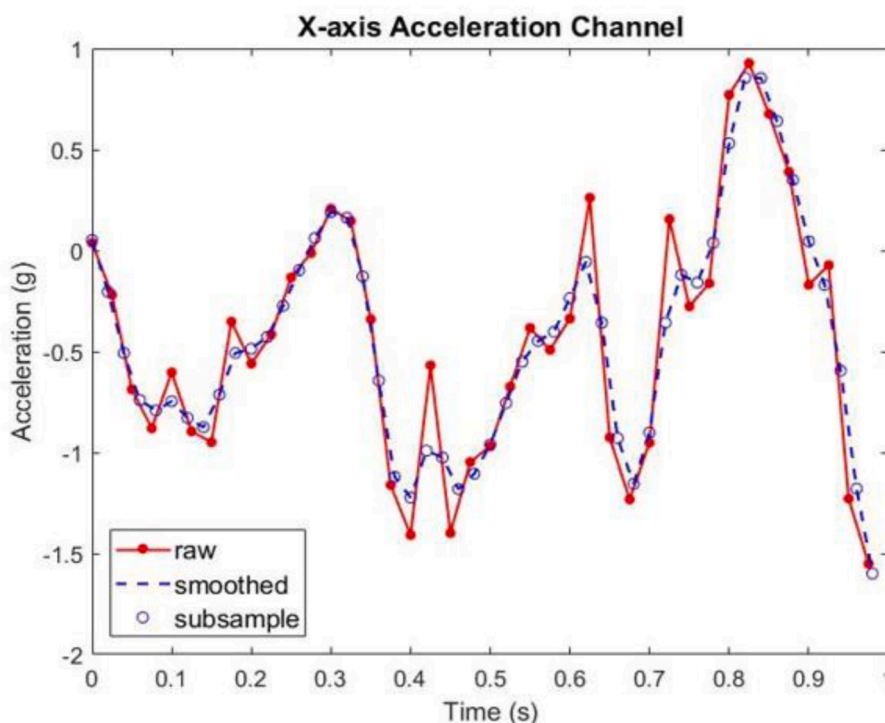

Figure 2. Preprocessing may include segmenting the data into equal time intervals and smoothing across the intervals to reduce noisy data.

deviations (Shepard et al., 2008). Alternatively, principal components analysis (PCA) can be used to compress the data but retain the critical characteristics of the data (Górecki and Krzyśko, 2012; Appendix VI: 7). The processed data are then paired to their respective direct behavioral observations by their shared dates and times to construct a time-series of dimensionally reduced accelerometer and/or magnetometer signals and their associated behaviors.

### 2.3. Machine learning for classification or clustering

We next must group the signals based on common signal structures and characterize them in terms of the behaviors observed for each signal type. This may be performed using either supervised or unsupervised machine learning algorithms, and the analyst may use whatever procedure is most appropriate for their data and hypotheses. Here we demonstrate behavioral classification using a common supervised algorithm (Random Forests; RFs), and signal clustering using a novel application of an uncommon unsupervised algorithm (Clustered Self-Organizing Maps; CSOMs). We chose these to demonstrate the robustness of the framework to the nuances and complexity of the selected procedure. Because RFs are increasingly common in ecology, we do not discuss details of RF-based analysis and instead direct interested readers to previous literature on these subjects (see Cutler et al., 2007; Ladds et al., 2017; Nathan et al., 2012).

SOMs are a type of unsupervised artificial neural network (ANN) and are comprised of two neural layers and their weighted connections (Chon, 2011; Kohonen, 2013; Appendix VI:8). Each input neuron, associated with an explanatory feature in the data, is exhaustively connected to all output neurons (cells on the map; Appendix I: Figure S1). Each cell represents data that share similar characteristics, and neighboring cells are generally more closely related than to more distant cells (Kohonen, 2013; Appendix I: Figure S2). SOMs learn by the exposure of data points to a randomly weighted (initialized) network. Each exposure for a total of  $N_{epoch}$  rounds results in a winning neuron (the weighted neuron that best matches the datapoint). During the initial covering phase, both the winning neurons and their neighbors are updated each round according to the initial covering ( $C$ , the number of times neighbors will be updated) and the initial neighborhood radius ( $r_{init}$ , which controls how many neighboring neurons are updated with the winning neuron). During this phase, the neighborhood radius will decrease incrementally from  $r_{init}$  to 1 to minimize overfitting (where  $r = 1$  is only the winning neuron and  $r = 2$  is the winning neuron and its immediate neighbors; Jafari-Marandi and Keramati, 2014). After the initial covering phase, only the winning neuron will be updated for the remaining rounds. Given an index for an updated neuron ( $i$ ), a winning neuron ( $c$ ), an exposure number ( $t$ ), an epoch number ( $T$ ), a model associated with neuron  $i$  at  $t$  ( $m_i(t)$ ), and a data point being exposed to the network ( $x(t)$ ), the model at time  $t + 1$  is:

$$m_i(t+1) = m_i(t) + h_i(T, c, r) \times [x(t) - m_i(t)]. \quad (1)$$

The sub-function  $h_i(T, c, r)$  controls the degree of change in the iterated model based on the proximity of neuron  $i$  to neuron  $c$  (the winning neuron), the epoch  $T$ , and the current neighborhood radius  $r$ .

The number of distinct signal types (cells on the map) is determined by the analyst. Determination of the optimal number of cells in the SOM for a given data set is the subject of much debate in the literature (Chon, 2011; Vesanto and Alhoniemi, 2000; Spanakis and Weiss, 2017). While there is no hard-and-fast rule, it is recommended to run SOMs with multiple grid sizes (Shalaginov and Franke, 2015). Regardless of grid size chosen, an objective approach is needed following SOM creation to identify the number of unique signal types that occur in the SOM. Because adjacent cells of the SOM are more similar than are more distant cells (Kohonen, 2013), we use  $k$ -means clustering to group similar cells into clusters (Jafari-Marandi et al., 2017; Vesanto and Alhoniemi, 2000; Appendix VI: 9). This approach produces a new CSOM wherein each cell is assigned a cluster based on its similarity to its neighbors and the

number of clusters ( $k$ ) to be identified (Fig. 3). Typically,  $k$ -means clustering requires  $k$  to be defined beforehand (Vesanto and Alhoniemi, 2000), but by using a silhouette analysis (Rousseeuw, 1987) conducted on a range of  $k$  we can eliminate subjectivity in cluster parameterization. Given  $k$  total clusters, the silhouette for a given cell  $i$  in cluster  $l$  is:

$$s_{i,l} = [\min(b_{i,j}) - a_{i,l}] / \max[a_{i,l}, \min(b_{i,j})], \quad (2)$$

where  $a_{i,l}$  is the average distance between cell  $i$  and all other cells in  $l$ , and  $b_{i,j}$  is the average distance between cell  $i$  and all cells within cluster  $j$  ( $j = 1, 2, \dots, k$ , excluding  $l$ ). The average silhouette ( $\bar{s}_l$ ) indicates within cluster similarity with values approaching 1 indicating appropriate and  $-1$  inappropriate clustering (Rousseeuw 1987). Because  $k$ -means clustering is sensitive to the starting observations at initialization (Vesanto & Alhoniemi, 2000), the datapoints must be randomized and the clustering repeated  $N_{rep}$  times with  $\bar{s}_l$  calculated for each cluster and each repetition. The value of  $k$  that maximizes the average  $\bar{s}_l$  across all  $N_{rep}$  trials ( $k_{best}$ ) is the optimal number of clusters (Appendix I: Figure S3).

After fitting the SOM and identifying the optimal number of signal types, we produce a clustering scheme whereby data in a SOM cell are assigned to the  $l$ -th cluster, and observations in  $l$  are as similar as possible. To determine the behaviors associated with each cluster and assess the discriminatory power of the scheme, we pair the observation time of the behaviors to the time of each clustered signal to identify the behaviors that occur in each cluster.

### 2.4. Behavioral probability matrix

We summarize the results of the classification and clustering procedures by constructing a probability profile describing the probability of observing each of the potential behaviors given that the data signal was categorized into a signal group (cluster or class). For either the RF or CSOM (or both), we may construct a  $n \times k$  matrix  $\mathbf{D}$  where each entry is the probability of observing the  $i$ th behavior in the  $j$ -th cluster/class. We then use  $\mathbf{D}$ , the probability profile, as our classifier to maintain the signal-specific behavioral variation. This matrix improves upon previous attempts at remote identification of animal behavior as it explicitly characterizes the probabilities of each behavior given a signal type (Nathan et al., 2012). To derive  $\mathbf{D}$ , we construct a  $n \times k$  contingency table from the behaviorally explicit data (matrix  $\mathbf{A}$ ) describing the proportion of each behavior-by-group combination relative to the entire data set, i.e.  $P(\text{behavior and group})$ . The summation of each column in  $\mathbf{A}$  produces a  $1 \times k$  vector  $\vec{B}$  that describes the probability of observing a signal group independent of the behaviors, i.e.  $P(\text{group})$ , and the summation of each row in  $\mathbf{A}$  produces a  $n \times 1$  vector  $\vec{C}$  that describes the probability of observing a behavior in the data set independent of the groups, i.e.  $P(\text{behavior})$ . We may calculate  $\mathbf{D}$  by dividing each entry in column  $j$  of  $\mathbf{A}$  by its associated column sum or value in  $\vec{B}$  (Fig. 4; Appendix VI:10). The resulting matrix  $\mathbf{D}$  represents the probability that a signal is associated with each behavior given that it was assigned to a specific group, i.e.  $P(\text{behavior}|\text{group})$  (Tables 1 & 2). To extend prediction to data for which there are no corresponding direct behavioral observations, (i.e. data whose true behaviors are unknown), we expose the new data to the model to obtain a class or cluster assignment. Assuming the training data is representative of new data, we can use  $\mathbf{D}$  from the original data to approximate the unknown profile  $\mathbf{D}^+$ .

### 2.5. Model validation

To test model performance and assess whether  $\mathbf{D}$  from the original data approximates the unknown profile  $\mathbf{D}^+$ , we must perform model validation. Validation is conducted using a resampling exercise whereby data with corresponding direct behavioral observations (hereafter termed the known behavioral data set) are randomly subsetted into test (holdout) and training (total excluding holdout) data sets (James et al.,

Figure 3. A clustered self-organizing map (CSOM) of wild pig (*Sus scrofa*) AM data with  $k=9$  clusters. Clusters are groups of related cells in the self-organizing map.

Matrix A (Proportional matrix)	Group 1	Group 2	...	Group k	Vector C (Behavior prop.)

2013, Ch. 5). For example, the test subset may contain  $n_{test} = 100$  random observations from the known behavior data set, and the remaining (training) data may be used to create a validation model. For the RF, we construct a classification matrix  $D_{train}$  using a RF algorithm applied to the training data, and the test data are subsequently exposed to the same RF to classify the holdout signals and construct the matrix  $D_{test}$  (Appendix VI: 14). For the SOM, we construct a validation SOM (vSOM) using the training data and the number of clusters  $k_{best}$  as determined by the general SOM (all known behavior) to maintain consistency across the iterations. The matrix  $D_{train}$  is constructed from vSOM, and the test data is then exposed to the vSOM to obtain cluster assignments and construct  $D_{test}$  (Appendix VI: 11 & 12). If the clustering

or classification system is effective, then on average  $D_{train}$  and  $D_{test}$  should be similar. To evaluate this, we calculate the  $L^1$ -norm ( $L^1$ ), a measure of matrix dissimilarity, between  $D_{train}$  and  $D_{test}$  (Paolini et al., 2018). Given  $n$  observed behaviors (i.e. the number of rows in D) and  $K$  clusters (i.e. the number of columns in D),  $L^1$  is the maximum across the  $K$  clusters:

$$L^1 = \max \left( \sum_{i=1}^n |D_{i,k}^{test} - D_{i,k}^{train}| \right), k = \{1, 2, \dots, K\}. \tag{3}$$

The theoretical interval of  $L^1$  as calculated here is [0,2], representing the cases where there is complete similarity ( $L^1 = 0$ ) and at least one

**Figure 5.** Validation is performed by randomly sub-setting training and test data sets such that the training set is used to estimate a behavioral classification model. The probability profile  $D_{train}$  is the expected behavioral proportions given that group  $k$  is observed. The test data is then exposed to the model to create the true probability profile of the test set  $D_{test}$ . We evaluate how well  $D_{train}$  approximates  $D_{test}$  by comparison using the standardized  $L^1$ -norm. By performing  $M$  iterations, we generate a distribution of standardized  $L^1$ -norms from which the average  $L^1$ -norm may be calculated.

column of complete dissimilarity ( $L^1 = 2$ ) between the test and training datasets (i.e., the behavior predicted and the true behavior are different). Thus, we divide  $L^1$  by 2 to produce  $\bar{L}^1$  such that 0 represents perfect similarity and 1 perfect dissimilarity between test and training data sets. If the test data are representative of the training data and if the algorithm accurately predicts new data, then over many iterations of this procedure using  $M$  randomly selected test/training sets we expect  $\bar{L}^1$  to approach 0 (Fig. 5). Note that  $L^1$  is inherently a conservative metric as it characterizes performance of  $\mathbf{D}$  only by its worst performing column. Alternatively, rather than the maximum one could use a standardized arithmetic mean for a metric that may better describe overall performance:

$$\bar{L}^{avg} = \sum_{k=1}^K \left( \sum_{i=1}^n |D_{i,k}^{test} - D_{i,k}^{train}| \right) / 2K. \quad (4)$$

## 2.6. Application to field data: wild pigs

We used an AM data set collected on wild pigs (*Sus scrofa*) in a semi-natural enclosure to demonstrate the application of this framework to field data. Biologging data was collected from wild pigs translocated to a 1 ha enclosure in Starkville, MS. The enclosure was equipped with 6 motion-activated infrared cameras synced to the internet to maintain accurate time. Seven wild pigs (3 males and 4 females) were captured and fitted with Daily Diary (DD) accelerometer and magnetometer data loggers (WildBytes Inc., Swansea, UK) sampling at 40 and 13 Hz, respectively. We include these data for demonstration purposes only and emphasize that further processing may be necessary for biological inference (e.g. by assessing different tri-axial rotation rules; see Brown et al., 2013; Shepard et al., 2008; Wilson et al., 2008).

Individual pigs were identified from videos and the time, behavior exhibited, and duration of behavior were recorded. Behaviors were classified into 5 broad categories in order of importance: (1) consumption, (2) resting, (3) environmental interaction, (4) locomotion, and (5) social interaction (Appendix II). We used a ranking system to ensure that we detected behaviors even if they commonly occurred with other behaviors (i.e. head down and consuming food continuously while walking would be classified as consumption). Each observation was “trimmed” (i.e. the first and last second removed), resulting in a 1 sec minimum for all observations. If a single behavior was interrupted by a brief bout of a different behavior (<2 s), whereafter the original behavior was resumed, the whole bout was classified as the first behavior. For example, a time series consisting of walking (5 s), freeze and scan for predators (1 s), and resume walking (5 s) would be classified as locomotion (11 s). Behaviors were paired with DD data by using the video timestamp and the DD’s internal clock (synced prior to deployment).

Each second of DD data (7 channels: Acc X, Acc Y, Acc Z, Mag X, Mag Y, Mag Z & VeDBA at ~40 Hz/channel) was smoothed using a cubic polynomial spline ( $\lambda = 1$ ) and resampled evenly from each curve (7 channels x 50 samples/s = 350 measurements/s). A PCA was performed on the samples for each of the 7 data channels, and the first 3 principal component vectors (PCs; 95–99% of the variation) per channel were selected for subsequent analysis (7 channels x 3 PCAs: 21 PCAs). A 20 × 20 SOM was parameterized with  $r_{init} = 3$ ,  $C = 30$ , and  $N_{epoch} = 200$ , and  $k$ -means clustering was performed using  $k = 3, 4, \dots, 25$  ( $N_{rep} = 3000$ ; see Appendix IV for additional analyses using alternative grid sizes). The RF was fit with 500 trees.

8418 videos of 7 captive wild pigs were recorded and classified manually, resulting in 75,601 s (21 h, ~3 hrs/pig) of observed behavior from 5 behavioral categories. Only biologging data for which there was a corresponding behavioral observation were used in the analysis. The number of observed behaviors in each group were tallied and matrices  $\mathbf{A}$  and  $\mathbf{D}$  and vectors  $\vec{B}$  and  $\vec{C}$  were constructed. Data cleaning, pairing and analyses were conducted in Daily Diary Multi Trace v. 25/Feb/2018 (WildBytes, Inc.), Program R v. 3.3.1 (R Core Team, 2016; Appendix VI:

1:3,10,12:14) and MATLAB 2017a (The MathWorks Inc 2017a, Appendix VI: 4:9, 11, 15). The Random Forests were fit with the randomForest package (Liaw and Wiener, 2002; Appendix VI: 13:14).

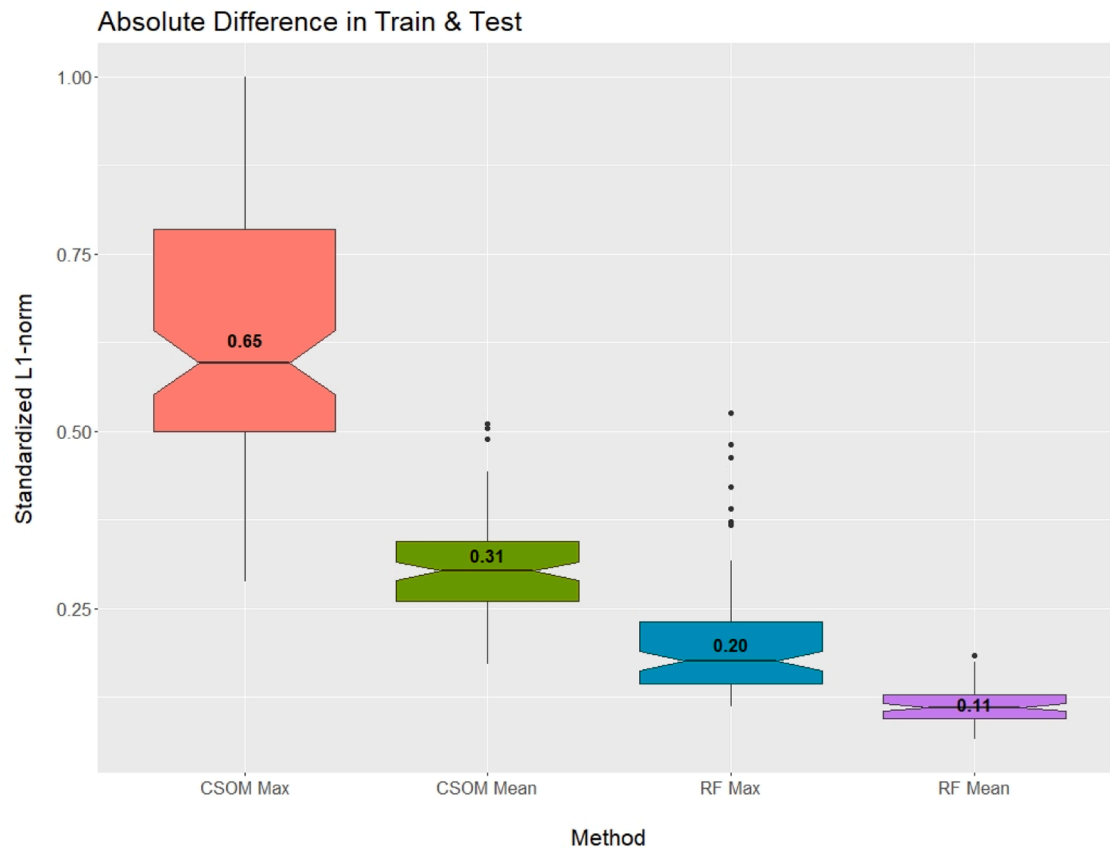

## 3. Results

As proportions of the entire data set, environmental interaction (37.62%) and locomotion (25.90%) were the most observed behaviors, followed by consumption (17.76%), resting (11.52%) and social interaction (7.21%). The average silhouette for the general SOM was maximized at  $k = 9$  ( $\bar{s}_i = 0.4895$ ; Appendix I: Figure S3). The Random Forest converged after 100 trees.

For the RF method, there was an overall 22% out-of-bag error rate irrespective of class. Each group was best predicted by a single behavior ranging from 97% (resting) to 70% (locomotion; Table 1). The “consumption” group (group 1) was most likely to be the consumption behavior (76%) followed by locomotion behavior (15%). The “locomotion” group (group 2) was most likely to be a locomotion behavior (70%) followed by a consumption behavior (17.5%). The “environmental interaction” group (group 3) was most likely to be an environmental interaction behavior (74%) followed by a consumption behavior (16%). This might suggest that behaviors associated with consumption in wild pigs produce several variable signals with some that appear more similar to a locomotion or environmental interaction signal than most consumption signals. This might be explained by blended signals where an animal is consuming food and thus its behavior is classified under consumption but is simultaneously walking or scanning (locomotion or environmental interaction respectively).

For the CSOM method, the clusters represented diverse behaviors with a high proportion of clusters that predicted behavioral combinations rather than a single behavior. Only 4/9 total clusters exhibited a > 50% probability for a single behavior (2 environmental interaction, 1 locomotion, 1 consumption; Table 2). The remaining clusters had a dominant behavior that was larger than the other behaviors but <50% of the total probability of the cluster (3 environmental interaction, 1 locomotion, 1 resting). Environmental interaction was the most prevalent behavior in our data and was either the most or second most probable in all clusters. This may indicate that the CSOM struggled to distinguish environmental interaction from the other behaviors perhaps because the primary behaviors that compose environmental interaction (i.e. sniffing, scanning) may not have particularly distinctive signals. Further, pigs frequently interrupted one behavior with brief bouts of other behaviors that may have introduced variation in our classification system or produced blended signals making it difficult to separate the behaviors into discrete categories. Locomotion was the second most prevalent behavior with the majority probability in clusters 2 and 8 and was second most probable in 3 clusters. Many non-locomotive behaviors were frequently accompanied by meandering (slow tortuous movement) which may share similar signal characteristics to walking (locomotion) or were punctuated by bouts of walking which may mask the other behavior’s signals completely. Consumption composed 60% of cluster 3 and resting behavior was the most prevalent in cluster 9 at 38%. Although social interaction did not dominate any cluster, it was the second most likely behavior at 25% in cluster 1.

The resampling procedure showed that there was an average maximum cluster dissimilarity of  $\bar{L}^1 = 0.65$  or 65% between the training and test data sets and an average mean cluster dissimilarity of  $\bar{L}^{avg} = 0.31$  or 31% using the CSOM, and an average maximum cluster dissimilarity of  $\bar{L}^1 = 0.20$  or 20% and an average mean cluster dissimilarity of  $\bar{L}^{avg} = 0.11$  or 11% for the RF (Fig. 6). This may be interpreted as 35% similarity between the test and training probability matrices for the CSOM method and 80% similarity for the RF method, indicating that the RF approach better predicted new data even though the hold-out data was 1/1000th the size of the training data. This is good evidence to conclude that the RF, on average, accurately predicted new data, and

**Figure 6.** The distribution of the maximum and average group dissimilarity (standardized  $L^1$ -norm; L1) for the CSOM and RF methods.

that the clusters identified as most distinctive by the  $20 \times 20$  CSOM method did not match our assigned behavioral labels. Thus, by performing this crucial validation step, we can conclude that matrix  $\mathbf{D}$  obtained from the trained RF, but not the CSOM, can be used to approximate the probabilistic behavioral profiles  $\mathbf{D}^+$  from unobserved data (but see Appendix IV for additional CSOM analyses).

#### 4. Discussion

Behavior is an important but often overlooked tool in interpreting animal distributions (Abrahms et al., 2017; Roever et al., 2014), and a variety of approaches have been used to link animal behavior to data sets of acceleration (Brown et al., 2013; Wilson et al., 2008). Here, we presented a probabilistic framework for interpreting animal behavior classified or clustered from AM signals. We applied two machine learning techniques: one supervised, where behaviors were paired with accelerometer data prior to classification, and one unsupervised, which first clustered the signals and then used the observed behaviors (Sakamoto et al., 2009; Chimienti et al., 2016; Nathan et al., 2012). Both approaches ultimately produce a matrix identifying the probability of observing a behavior given a known acceleration signal (Fig. 3, Tables 1 & 2) but validation showed that the CSOM method performed poorly and thus the probability profile cannot be trusted. Though most current approaches assign a signal type to a target behavior (Nathan et al., 2012), the RF showed many behaviors exhibited similar data signals, and several groups were likely to reflect multiple rather than single behaviors. This may be because some behaviors may be difficult to discriminate using collar attached accelerometers (e.g., Nathan et al., 2012; Wang and Xu, 2015) and by using a probability profile, we accommodate this explicitly.

Quantifying the variation in animal behaviors across landscapes is crucial for our understanding of animal movement (Johnson, 1980;

Matthiopoulos et al., 2015; Nathan et al., 2008; Van Horne, 1982). Animals may use a single landscape for multiple purposes, complicating the ability of researchers to predict a single behavior from landscape features (Street et al., 2016). Using a probability profile accounts for this but also allows for the empirical calculation of multiple behavioral probabilities for any landscape. Thus, this may be used to estimate the relative probability that an animal will engage in a behavior provided an environmental context. Conceptually similar to a Resource-Selection Function (RSF; Boyce and McDonald, 1999), one could estimate the probability of observing the behavior given a suite of covariates and thus predict the relative probability of observing a given behavior in space and time. We foresee 2 general approaches to producing such a model. First, a simple logit model as commonly applied to e.g., RSFs could produce the desired spatial model of behavior. However, the very high refresh rates for accelerometers (e.g., 1+ Hz) will typically produce many behavioral observations at a given spatial location, particularly if the resolution of the spatial layers is large (as is common for remotely sensed landscape data products). Application of logit models will thus require researchers to consider how best to accommodate what is a clear violation of independence for such a model. This could be accomplished by sub-sampling data to a single observation per pixel, or by aggregating/averaging probabilities for behaviors within a given pixel. Neither outcome is particularly appealing due to loss of information, but the resulting logit models are well described in the literature and have ample tools for model validation, calibration, and sensitivity (e.g., Chivers et al., 2014; Harrell, 2016). Alternatively, Hidden Markov Models (HMMs) have been recently applied to accelerometry data (Leos-Barajas, 2017). Though far less common than standard logit models, these or similar models that incorporate autocorrelation structures (e.g., temporal autoregressive models; Hooten et al., 2017) could be used to generate the desired spatial models while accommodating dependence between consecutive observations.

Provided that we have a properly parameterized probabilistic spatial model of behavior, multiplicative pairing of such models with simple models of space use (e.g., RSFs) combines the relative probability of occurrence with the relative probability of observing different behaviors in that location. Akin to a utilization kernel for animal behavior, this “behavior kernel” should reflect the relative probability of a known behavior, weighted by the probability of the animal using that space (Worton, 1989). These models, enabled by the probabilistic framework presented here, may offer tremendous opportunities for new insight. For example, the Ideal Free Distribution (IFD) posits the equilibrium distribution of a population will be achieved when all individuals have equal fitness relative to local density and environmental quality (Fretwell and Lucas, 1969). If animal fitness may be thought of as an energy budget whereby animals must balance energetic costs with inputs (Brown et al., 2004), then we should expect that animal fitness will be highest in areas where energy intake exceeds expenditure. These areas of high relative fitness should be identifiable following the two-stage model described above as locations with high probabilities of occurrence and of behaviors promoting energy intake. We expect that the behavior kernel will strongly correlate with the IFD and provide a mechanistic link between the behaviors of individuals and the distributions of populations, a longstanding goal of predictive ecology (Matthiopoulos et al., 2015).

One concern with our approach is that the model may not accurately represent the behavioral probabilities of new data (Yates et al., 2018). By performing a resampling exercise and using the  $L^1$  matrix-based statistic, we observed that data withheld from the RF were accurately classified but the CSOM method did not accurately identify new data. Thus, the CSOM model overall did not perform well and thus, is not suitable for either the direct assignment or probability profile approach. Our approach acknowledges that behaviors with similar characteristics should be difficult to identify in any machine learning approach. Although this problem may be more pronounced in unsupervised learning algorithms (Nathan et al., 2012), it is a common challenge of working with behavioral data. We emphasize that the type of machine learning technique used should be dictated by the questions the analyst has for the data set; however, use of a probability profile rather than a direct assignment can be adopted regardless of the algorithm used to group the data provided that the model validates well.

It is also worth noting that the apparent poor performance of the CSOM may be attributed to the validation metric  $L^1$ . This metric is mathematically well described and is calculated as the maximum observed summed difference between entries of the columns of two matrices. If two matrices are identical save for a single column,  $L^1$  bases dissimilarity only on the differing column.  $L^1$  is thus a highly conservative metric of matrix dissimilarity that may be interpreted as the maximum dissimilarity observed across signal types. By contrast, we may instead evaluate matrix dissimilarity using the arithmetic mean of the summed differences between columns rather than the maximum. This metric is no longer conservative but may be a better reflection of overall performance when few signal types perform poorly. Indeed, the average summed differences showed overall better agreement between  $D_{\text{test}}$  and  $D_{\text{train}}$  than suggested by  $L^1$  for the both the CSOM and RF approaches (Fig. 6). Selection of the validation metric should be determined by the specific needs of the project and the degree of predictive accuracy desired.

There was likely some error in label assignment as it was difficult to identify individual pigs and to temporally synchronize DD observations to videos. Additionally, the behavioral proportions observed via video may not represent the true frequency of pig behavior in the enclosure and may differ from those of wild pigs (Burghardt et al., 2012). Because captive pigs were supplied with food, they may spend less time engaging in consumption behaviors as their wild counterparts (Grandia et al., 2001). However, of critical concern is the possibility that certain behaviors may not be represented in the training data (e.g., swimming). For such cases, our system would be incapable of identifying these

behaviors. We reiterate that data need to be representative of the total variation in data signals and behaviors and emphasize that validation is critical for any remote sensing exercise (Congalton, 1991; Nathan et al., 2012).
